# Heuristics for a Matrix Symmetrization Problem* 

Bora Uçar<br>CERFACS,<br>42 Avenue Gaspard Coriolis, 31057, Toulouse, Cedex 1, France<br>ubora@cerfacs.fr

#### Abstract

We consider the following problem: given a square, nonsymmetric, $(0,1)$-matrix, find a permutation of its columns that yields a zero-free diagonal and maximizes the symmetry. The problem is known to be NP-hard. We propose a fast iterative-improvement based heuristic and evaluate the performance of the heuristic on a large set of matrices.

Keywords: unsymmetric sparse matrix, bipartite matching, matrix symmetrization.

## 1 Introduction

We consider the matrix symmetrization problem for square $(0,1)$-matrices. A square matrix $A$ is symmetrizable if its columns can be permuted to yield a symmetric matrix. Deciding whether a given matrix is symmetrizable is NP-complete [4]. The variation of the problem which restricts the permutations such that the permuted matrix has a zero-free diagonal is also NP-complete [2]. In this work, we are interested in the optimization version of the matrix symmetrization with zero-free diagonal problem, i.e., given a square ( 0,1 )-matrix, find a permutation of the columns that yields a zero-free diagonal and maximizes the symmetry. We assume that there is at least one permutation that yields a zero-free diagonal.

The problem arises in a preprocessing phase of some other algorithms. For example, when a given sparse matrix $A$ has an unsymmetric pattern, most of the graph partitioning and ordering algorithms are applied to the pattern of the symmetric completion $A+A^{T}$ (ignoring numerical cancellation); see discussions in 810 15. A remark which usually accompanies using the pattern of the symmetric completion is that this trick would be appropriate only if the matrix is nearly symmetric. The techniques proposed in this work can be used to make a given matrix more symmetric and obtain a sparser symmetric completion. In other words, the proposed techniques can help improve the running time of the aforementioned algorithms and their solutions' quality.

Since the decision problem is NP-complete, and hence the optimization version that we are interested is NP-hard, we propose a heuristic algorithm. We test the heuristic on a large set of matrices. We also report encouraging experiments on a certain matrix ordering problem.

## 2 Method Description

In this section, $A$ is a square $(0,1)$-matrix of size $n \times n$. As is common, we associate a bipartite graph $G=(R \cup C, E)$ with the matrix $A$, where $R$ and $C$ are the two sets in the vertex bipartition, and $E$ is the set of edges. Here, the vertices in $R$ and $C$ correspond, respectively, to the rows and the columns of $A$ such that $\left(r_{i}, c_{j}\right) \in E$ if and only if $a_{i j}=1$. Although the edges are undirected, we will always specify an edge $e \in E$ as $e=\left(r_{i}, c_{j}\right)$; the first vertex will always be a row vertex and the second one will always be a column vertex. An edge $e=\left(r_{i}, c_{j}\right)$ is called to be incident on the vertices $r_{i}$ and $c_{j}$. We have the following notation: $N\left(r_{i}\right)$ denotes the neighbors of a row vertex $r_{i}$, i.e., $N\left(r_{i}\right)=\left\{c_{j}:\left(r_{i}, c_{j}\right) \in E\right\}$; similarly $N\left(c_{j}\right)=\left\{r_{i}:\left(r_{i}, c_{j}\right) \in E\right\}$ denotes the neighbors of a column vertex $c_{j}$; for a set $s,|s|$ denotes its cardinality; $d(\cdot)$ denotes the degree of a vertex, e.g., $d\left(r_{i}\right)=\left|N\left(r_{i}\right)\right|$; and $w_{i j}$ denotes the weight of an edge $\left(r_{i}, c_{j}\right)$.

We recall some standard definitions and well-known results. An even cycle contains an even number of vertices. A set of edges $\mathcal{M}$ is a matching if no two edges in $\mathcal{M}$ are incident on the same vertex. Given a matching $\mathcal{M}$, an $\mathcal{M}$ alternating cycle is a simple cycle whose edges are alternately in $\mathcal{M}$ and not in $\mathcal{M}$. A matching is called perfect if for any vertex $v$ in $G$, there is an edge in $\mathcal{M}$ incident on $v$. If the edges are weighted, then the weight of a matching $w(\mathcal{M})$ is equal to the sum of the weights of its edges, i.e., $w(\mathcal{M})=\sum_{\left(r_{i}, c_{j}\right) \in \mathcal{M}} w_{i j}$. A maximum weight perfect matching on a weighted graph is a perfect matching with maximum weight. Both the perfect matching problem and the maximum weight perfect matching problem are efficiently solvable [7|13]. We use mate ( $v$ ), to denote the vertex matched to the vertex $v$ in a matching $\mathcal{M}$. That is if $\left(r_{i}, c_{j}\right) \in \mathcal{M}$, then $\operatorname{mate}\left(r_{i}\right)=c_{j}$ and $\operatorname{mate}\left(c_{j}\right)=r_{i}$. It is well known that perfect matchings in the bipartite graph $G$ correspond to permutations which yield zero-free diagonals, see for example [7]. A matching edge $\left(r_{i}, c_{j}\right)$ is used to permute the column $c_{j}$ to the $i$ th position, yielding a zero-free diagonal. This is achieved by defining the permutation matrix $M$ as

$$
m_{i j}= \begin{cases}1 & \left(r_{i}, c_{j}\right) \in \mathcal{M} \\ 0 & \text { otherwise }\end{cases}
$$

and then by multiplying $A$ on the right by $M$, i.e., by forming $A M$. We will use calligraphic letters for perfect matchings, e.g., $\mathcal{M}$, and the corresponding italic, Roman letters, e.g., $M$, for the associated permutation matrices.

For a given square $(0,1)$-matrix $A$, we define the symmetry score as

$$
\begin{equation*}
S(A)=\sum_{a_{i j} \neq 0} a_{i j} a_{j i} \tag{1}
\end{equation*}
$$

As seen from the formula each nonzero entry $a_{i j}$ contributes either 0 or 1 to the score. Hence, for a symmetric matrix $A, S(A)$ is equal to the number of its nonzeros. For a given column permutation $M, S(A M)$ measures the symmetry score of the permuted matrix.

### 2.1 The Heuristic

We propose an iterative-improvement-based heuristic. The proposed heuristic works on the bipartite graph representation of a given matrix. It starts with a perfect matching to guarantee a zero-free diagonal, and then iteratively improves the current matching to increase the symmetry while maintaining a perfect matching at all times.

```
Algorithm 1. Compute the symmetry score
Input: a bipartite graph \(G=(R \cup C, E)\) corresponding to an \(n \times n\) matrix \(A\)
Input: a perfect matching \(\mathcal{M}\)
Output: score \(=S(A M)\)
    \(\operatorname{mark}(r) \leftarrow 0\) for all \(r \in R\)
    score \(\leftarrow 0\)
    for each \(\left(r_{i}, c_{j}\right) \in \mathcal{M}\) do
        for each \(c \in N\left(r_{i}\right)\) do
            \(\operatorname{mark}(\operatorname{mate}(c)) \leftarrow j \quad \triangleright \operatorname{mark} r_{i}\) too
        for each \(r \in N\left(c_{j}\right)\) do
            if \(\operatorname{mark}(r)=j\) then
                score \(\leftarrow\) score \(+1 \quad \triangleright\) increase by one for \(\left(r_{i}, c_{j}\right)\),
                    \(\triangleright\) also for a symmetric entry \(\left(r_{k}, c_{j}\right) \notin \mathcal{M}\)
                    \(\triangleright\) with \(r_{k}=\operatorname{mate}(c)\) for a \(c \in N\left(r_{i}\right)\)
```

Given a perfect matching $\mathcal{M}$, the symmetry score of the permuted matrix $A M$ can be computed as shown in Algorithm The algorithm runs in $O(E)$ time, since the edges incident on a vertex $v$ are visited only when the matching edge incident on $v$ is processed at line 3 .

Note that for a matching edge $\left(r_{i}, c_{j}\right) \in \mathcal{M}$, the test at line 7 holds, and the matching edge (a diagonal entry in the permuted matrix $A M$ ) contributes one to the score. Consider two matching edges $\left(r_{i}, c_{j}\right)$ and $\left(r_{k}, c_{l}\right)$ such that $\left(r_{i}, c_{l}\right) \in E$ and $\left(r_{k}, c_{j}\right) \in E$. These four edges form an $\mathcal{M}$-alternating cycle of length four, and herald two off-diagonal symmetric entries in addition to the two diagonal entries in $A M$. The score is incremented by 2 for those two off-diagonal symmetric entries in two steps; by 1 when the "for loop" at line 3 is processing $\left(r_{i}, c_{j}\right)$, and by 1 while the "for loop" at line 3 is processing $\left(r_{k}, c_{l}\right)$. Let $C 4$ be the set of unique alternating cycles of length four, then the score will be

$$
\begin{equation*}
S(A M)=n+2 \times|C 4| . \tag{2}
\end{equation*}
$$

Note that all perfect matchings will result in a symmetry score of at least $n$, therefore the number of alternating cycles of length four is the important term.

Let $\mathcal{M}^{\star}$ and $\mathcal{M}$ be, respectively, an optimal perfect matching maximizing the symmetry score, and another perfect matching on the bipartite graph $G$. Then the symmetric difference $\mathcal{M}^{\star} \oplus \mathcal{M}=\left(\mathcal{M}^{\star} \backslash \mathcal{M}\right) \cup\left(\mathcal{M} \backslash \mathcal{M}^{\star}\right)$ contains only isolated vertices and even cycles. This is because a given vertex is incident on exactly one edge of $\mathcal{M}$ and one edge of $\mathcal{M}^{\star}$; if those edges are the same, then
the vertex becomes isolated, otherwise it becomes a part of a cycle (intrinsically an even cycle as the graph is bipartite). Note that each such cycle is an $\mathcal{M}$ alternating cycle. Therefore, an optimal solution $\mathcal{M}^{\star}$ can be obtained from any perfect matching $\mathcal{M}$ by finding $\mathcal{M}$-alternating cycles and then reversing the membership of the edges along those cycles. Note that this does not imply an efficient algorithm, as there are combinatorially many alternating cycles with respect to a given matching.

Having observed the role of the alternating cycles in improving a given matching, and having noted Eq. 2, we propose to work on the alternating cycles of length four to improve a given perfect matching. Similar to some other iterative-improvement-based heuristic, such as that in [12], we organize the refinement process in passes. At each pass, we build the set $C 4$ of unique alternating cycles of length four using an algorithm much like Algorithm [1. Then, we visit the unique alternating cycles of length four in a random order. Among the cycles those whose vertices are not affected by a previous operation and with a nonnegative effect on symmetry score are reversed. That is, in a four cycle, the matching edges are replaced by the non-matching ones. Algorithm 2 shows the actions taken within a pass.

```
Algorithm 2. Refine a perfect matching
Input: a bipartite graph \(G=(R \cup C, E)\) corresponding to an \(n \times n\) matrix \(A\)
Input: a perfect matching \(\mathcal{M}^{(0)}\)
Output: another perfect matching \(\mathcal{M}^{(1)}\) where \(S\left(A M^{(1)}\right) \geq S\left(A M^{(0)}\right)\)
    \(\mathcal{M}^{(1)} \leftarrow \mathcal{M}^{(0)}\)
    \(C 4 \leftarrow\left\{\left(r_{1}, c_{1}, r_{2}, c_{2}\right):\left(r_{1}, c_{1}\right) \in \mathcal{M}^{(1)}\right.\) and \(\left(r_{2}, c_{2}\right) \in \mathcal{M}^{(1)}\) and
                                    \(\left(r_{1}, c_{2}\right) \in E\) and \(\left.\left(r_{2}, c_{1}\right) \in E\right\}\)
    while \(C 4 \neq \emptyset\) do
        pick a cycle \(\mathcal{C}=\left(r_{1}, c_{1}, r_{2}, c_{2}\right) \in C 4\)
        if isReversible \((\mathcal{C})\) and gain \((\mathcal{C}) \geq 0\) then
            \(\mathcal{M}^{(1)}=\mathcal{M}^{(1)} \oplus \mathcal{C}\)
        remove the cycle \(\mathcal{C}\) from \(C 4\)
```

The test isReversible $(\mathcal{C})$ returns true if none of the vertices $\left\{r_{1}, c_{1}, r_{2}, c_{2}\right\}$ has been moved before. In other words, this test returns true if the current matching contains the edges $\left(r_{1}, c_{1}\right)$ and ( $r_{2}, c_{2}$ ). The gain computations are done by using the main "for loop" of Algorithm 1 for the edges $\left(r_{1}, c_{1}\right)$ and $\left(r_{2}, c_{2}\right)$, and then for the edges $\left(r_{1}, c_{2}\right)$ and $\left(r_{2}, c_{1}\right)$. The difference between the returned scores gives the gain of reversing the edges in the cycle $\mathcal{C}$.

In the worst case, all gain computations return negative, Algorithm 2 evaluates the gain of all alternating cycles of length four. We first note that a vertex $v$ can be in at most $d(v)-1$ alternating cycles of length four, because one of its neighbors in all such cycles should be its mate. For each such cycle, the edges incident on $v$ are visited during gain computations. Therefore, the gain computation operations can spend at most $O\left(d(v)^{2}\right)$ time on a vertex $v$. Hence the worst case total time can be bound as $O\left(\sum_{r \in R} d(r)^{2}+\sum_{c \in C} d(c)^{2}\right)$. In practice a faster worst case running time can be expected. This is because of
two reasons. First, there are negative terms adding up to $O(|E|)$ that we omit. Second, the number of length four alternating cycles containing a vertex $v$ cannot be larger than $d(\operatorname{mate}(v))-1$.

We make the following observations: (1) the set of alternating cycles of length four, $C 4$, is constructed according to the initial matching; (2) each cycle in $C 4$ is considered at most once; (3) due to the nonnegative gain requirement, the algorithm cannot escape from a local minimum. Having observed these deficiencies, we designed two alternatives. The first alternative starts with the same set $C 4$ as in Algorithm 2 with more involved data structures and operations. It maintains $C 4$ as a priority queue using the gain of a cycle as its key; tentatively modifies the current matching along the best cycle, even along those with a negative effect; at the end, realizes the most profitable prefix of modifications. This approach obtained better results than Algorithm 2, with increases in running time. The second alternative visits the row vertices in a random order, computes the best length four alternating cycle containing that vertex, and modifies the current matching along that cycle if the gain is nonnegative. Algorithm 2 outperformed this alternative in terms of solution quality.

Another point worth mentioning is that computing the block triangular form (btf) of matrix can help reduce the running time of the algorithm. It is well known that the entries outside the diagonal blocks of a btf cannot belong to a perfect matching; see for example [6, Chapter 6] and [14]. Therefore, the corresponding edges in the bipartite graph $G$ cannot belong to an alternating cycle. Those edges can be discarded without any effect on the solution quality of the proposed algorithm to reduce the running time.

### 2.2 Upper Bounds and Initial Matching

Consider a row $r_{i}$ and a column $c_{j}$ where $a_{i j}=1$. For any matching $\mathcal{M}$ with $\left(r_{i}, c_{j}\right) \in \mathcal{M}$, the contribution of the matching edge $\left(r_{i}, c_{j}\right)$ to $S(A M)$ is limited by $\min \left\{d\left(r_{i}\right), d\left(c_{j}\right)\right\}$, or, equivalently by the smaller of the number of nonzeros in the corresponding row and column of $A$. Consider a maximum weight perfect matching $\mathcal{M}_{B 1}^{\star}$, subject to edge weights $w_{i j}=\min \left\{d\left(r_{i}\right), d\left(c_{j}\right)\right\}$, in the bipartite graph $G$. The weight $w\left(\mathcal{M}_{B 1}^{\star}\right)$ defines an upper bound, referred to as UB1, on the attainable symmetry score. We further obtain an improved upper bound by observing that all neighbors of the vertex $r_{i}$ may not be matchable to the neighbors of $c_{j}$ (or vice versa). In fact, two vertices $r_{i}$ and $c_{j}$ can contribute at most by the weight of the maximum weight matching $\mathcal{M}_{i j}^{\star}$, subject to unit edge weights, in the induced subgraph $G_{i j}=\left(N\left(c_{j}\right) \cup N\left(r_{i}\right), E \cap N\left(c_{j}\right) \times N\left(r_{i}\right)\right)$. Consider a maximum weight perfect matching $\mathcal{M}_{B 2}^{\star}$, subject to edge weights $w_{i j}=w\left(\mathcal{M}_{i j}^{\star}\right)$, in $G$. The weight $w\left(\mathcal{M}_{B 2}^{\star}\right)$ defines an upper bound, referred to as UB2, on the attainable symmetry score.

Both of the perfect matchings $\mathcal{M}_{B 1}^{\star}$ and $\mathcal{M}_{B 2}^{\star}$ can be used as an initial solution. Note that we have $w\left(\mathcal{M}_{B 2}^{\star}\right) \leq w\left(\mathcal{M}_{B 1}^{\star}\right)$. However, we do not have any relation between the resulting symmetry scores. The CPU cost of finding $\mathcal{M}_{B 2}^{\star}$ can be very high. Therefore, we prefer using $\mathcal{M}_{B 1}^{\star}$ as an initial solution.

## 3 Experiments

We present results with two sets of square matrices from University of Florida Sparse Matrix Collection [5]. Matrices in the first set originally have symmetric nonzero pattern and full sparse rank, and they satisfy the following assertions regarding the order $n$ and the number of nonzeros nnz: $n \geq 1000$, nnz $\leq 10^{6}$, $n n z \geq 3 \times n$. There were a total of 420 such matrices (out of 1840) at the time of writing. We ensured that the original matrices have zero-free diagonal. Then, we permuted the rows and columns of those matrices randomly and created unsymmetric matrices. If $B$ is the pattern of an original matrix, then the corresponding matrix $A$ in this set has the pattern of $P(B+I) Q$, where $I$ is the $n \times n$ identity matrix, and $P$ and $Q$ are random permutation matrices. That is, for a matrix $A$ in this set, the optimal symmetry score is equal to the number of nonzeros in $A$. The matrices in the second set are the 28 public domain matrices used in 715. These matrices are highly unsymmetric. There are four matrices with an original symmetry score greater than $0.4 \times$ nnz; however, there are zeros in the main diagonal. For these 28 matrices, we do not know the optimal symmetry score. We computed the upper bound UB2 for these matrices.

In the experiments, initial matching $\mathcal{M}^{(0)}$ is chosen to be $\mathcal{M}_{B 1}^{\star}$, the perfect matching that defines the upper bound UB1. We use mc64 (described in [7) from the mathematical software library HSL [9] with job=4 to compute $\mathcal{M}_{B 1}^{\star}$. The worst case time complexity of mc64 on an $n \times n$ matrix with $\tau$ nonzeros is $O\left(n(\tau+n) \log _{2} n\right)$. However, in practice it behaves much faster; see our experiments below and some others in [1] and [7.

We present the performance of the proposed algorithm by normalizing the symmetry score by the upper bound. In what follows, $\mathcal{M}^{(p)}$ is the final perfect matching obtained at the end of the $p$ th refinement pass. Table displays the minimum, the average, and the maximum normalized symmetry scores of $\mathcal{M}^{(0)}=\mathcal{M}_{B 1}^{\star}$ and $\mathcal{M}^{(p)}$ for $p \in\{1,3,5,7\}$ on 420 originally symmetric matrices. As seen from the average normalized scores, most of the improvements are obtained within the first few passes. In the remainder, we limit the number of refinement passes to five, i.e., we apply Algorithm 2 five times. As seen from the table, the average symmetry score 0.628 of $\mathcal{M}^{(0)}$ is improved by around $38 \%$ in five refinement passes, resulting in an average symmetry score of 0.872 for $\mathcal{M}^{(5)}$.

Figure 1 displays the histogram of the normalized symmetry scores for the initial matching $\mathcal{M}^{(0)}$ and the final matching $\mathcal{M}^{(5)}$. The final matching $\mathcal{M}^{(5)}$ obtained the optimal symmetry score for 89 matrices. The initial matching $\mathcal{M}^{(0)}$ obtained the optimal symmetry score only for 4 matrices. There are only 7 instances below 0.628 (the average for $\mathcal{M}^{(0)}$ ) among the normalized symmetry scores of $\mathcal{M}^{(5)}$.

We argue that the initial choice of using the perfect matching $\mathcal{M}_{B 1}^{\star}$ which attains the upper bound UB1 is an important part of the proposed algorithm. We show this by experimenting with two other initial perfect matchings. The first one is an arbitrary perfect matching $\mathcal{M}_{a}^{\star}$ on the bipartite graph $G$ (found using mc64 with job=1). The second one is the perfect matching $\mathcal{M}_{B 2}^{\star}$ which attains the upper bound UB2. For the originally symmetric matrices, the upper bound UB1 is ex-

Fig. 1. Histogram of the normalized symmetry scores for the initial matching $\mathcal{M}^{(0)}$ (white bars) and the final matching $\mathcal{M}^{(5)}$ (black bars)
act. Hence, UB2 and the associated matching coincide with UB1 and its matching. With an arbitrary initial perfect matching, the proposed algorithm obtained an average normalized symmetry score of 0.656 (minimum 0.073 and maximum 0.995), well below the average 0.872 given in the rightmost column of Table 1 For the originally unsymmetric matrices, the two upper bounds are different, therefore using the three initial matchings makes sense. The average normalized (with respect to UB2) score after five refinement passes starting from these initial matchings are 0.593 (with $\mathcal{M}_{a}^{\star}$ ), 0.655 (with $\mathcal{M}_{B 1}^{\star}$ ), and 0.699 (with $\mathcal{M}_{B 2}^{\star}$ ). Using $\mathcal{M}_{B 2}^{\star}$ as an initial matching resulted in a better average score with the alternative refinement method which uses priority queues (mentioned towards the end of Section2.1) too. However, on some matrices, it took hours to compute $\mathcal{M}_{B 2}^{\star}$. That is $\mathcal{M}_{B 1}^{\star}$ leads to results similar to those of $\mathcal{M}_{B 2}^{\star}$, and it is affordable.

For reproducibility of the results on originally unsymmetric matrices, we present the upper bound UB2 and our results in Table 2. The results are obtained by starting from the initial matching $\mathcal{M}^{(0)}=\mathcal{M}_{B 1}^{\star}$. On average, the symmetry score of the initial matching is improved by $20 \%$ at the end of the fifth refinement pass.

We implemented the algorithm in C, compiled with gcc using option -03, and performed the tests on a Pentium IV 2.80 GHz PC with 2 GB main memory and 1 MB cache. The running time of the proposed algorithm (with five refinement
passes) is, on average, 1.6 seconds for those matrices with a normalized initial symmetry score, $S\left(A M_{B 1}^{\star}\right) / \mathrm{UB} 2$, less than 0.9 . For others, it takes much larger. The largest running time was obtained for the matrix ASIC_100k ( $n=99340$, $n n z=940696$ ) having an initial normalized score of 0.912 (final score is 0.998). For this matrix, the running time is almost an hour. The running time of the HSL subroutine mc64 is, on average, 0.9 seconds. Therefore, we suggest computing the perfect matching $\mathcal{M}_{B 1}^{\star}$, checking its symmetry score, and proceeding with 3-to-5 refinement passes if the initial result is not satisfactory.

We have tested the effects of the proposed heuristic on the problem of ordering a matrix to doubly bordered block diagonal form. Given a matrix and an integer $K$, the aim is to permute the matrix into $(K+1) \times(K+1)$ block form such that

Table 2. Symmetry scores for originally unsymmetric matrices. Matrices in the top block are from [7]; those in the bottom block are from [15]. The upper bounds (UB2) on the symmetry score are not guaranteed to be attainable. The matrices originally have zeros on the main diagonal, therefore we do not display their original symmetry score.

there is no nonzero in blocks $(k, \ell)$ and $(\ell, k)$ for $1 \leq k<\ell \leq K$, the diagonal blocks $(k, k)$ for $1 \leq k \leq K$ are square and have almost equal order. The cost is the size of the border, i.e., the order of the $(K+1, K+1)$ st block. The problem is NP-hard 3]. A common tool used for this task is MeTiS [11. MeTiS finds the block form using symmetric permutations. The heuristics used in MeTiS works on symmetric matrices. Therefore, the trick of using the pattern of $A+A^{T}$ (no numerical cancellation) instead of $A$ is applicable here. We tested MeTiS on the matrices given in Table 2 with $A+A^{T}$ and $A M^{(5)}+\left(A M^{(5)}\right)^{T}$ for $K=4,8,16,32,64$. Using $A M^{(5)}$ resulted in, on average, $43 \%$ smaller border size than using $A$, with, on average, $36 \%$ reduction in the running time. In 110 instances out of 140, using $A M^{(5)}$ resulted in better results than using $A$. The best reduction, 114 versus 8288, is obtained for bayer01 with $K=4$. The worst increase, 6726 versus 3997 was obtained for sinc15 with $K=64$; this was an odd case-MeTiS gave almost the same border size for $K=4,8,16,32,64$ when using $A$.

## 4 Conclusion

We proposed a heuristic to solve the matrix symmetrization with zero-free diagonal problem. The heuristic starts from a judiciously chosen initial solution and iteratively improves it. We presented experiments on two sets of matrices. We know the optimal solution for the matrices in one of the sets. The solutions found by the proposed heuristic are, on average, around 0.87 of the exact solutions for the 420 matrices in this set. We do not know an optimal solution for the matrices in the other set. Therefore, we compared the solution quality with respect to a an upper bound described in the paper. The proposed heuristic achieved solutions, on average, within 0.70 of the upper bounds for the matrices in the second set. Compared to the average achieved for the matrices in the first set, we think that the latter results are lower due to having a loose upper bound.

## Acknowledgments

I thank M. Benzi, I. S. Duff, O. Parekh, and S. Pralet for helpful discussions, an anonymous referee for constructive comments which helped improve the presentation of Section 3 ,
